

Robust Digital Envelope Estimation Via Geometric Properties of an Arbitrary Real Signal

Carlos Tarjano

Valdecy Pereira

September 5, 2020

Abstract

Despite being an elusive concept, the temporal amplitude envelope of a signal is essential for its complete characterization, being the primary information-carrying medium in spoken voice and telecommunications, for example. Intuitively, the temporal envelope can be understood as a smooth function that multiplies the signal, being responsible for its outer shape. Envelope detection techniques have applications in areas like health, sound classification and synthesis, seismology and speech recognition. Nevertheless, a general method to digital envelope detection of signals with rich spectral content doesn't exist, as most methods involve manual intervention, in the form of filter design, smoothing, as well as other specific design choices, based on a priori knowledge about the nature of the specific waves under investigation. To address this problem, we propose a framework that uses intrinsic characteristics of a signal to estimate its envelope, completely eliminating the necessity of parameter tuning. The approach here described draws inspiration from geometric concepts to isolate the frontiers and thus estimate the temporal envelope of an arbitrary signal; to that end, alpha-shapes, concave hulls, and discrete curvature are explored. We also define entities, such as a pulse and frontiers, in the context of an arbitrary digital signal, as a means to reduce dimensionality and the complexity of the proposed algorithm. Specifically, a new measure of discrete curvature is used to obtain the average radius of curvature of a discrete wave, serving as a threshold to identify the wave's frontier points. We find the algorithm accurate in the identification of the frontiers of a wide range of digital sound waves with very diverse characteristics, while localizing each pseudo-cycle of the wave in the time domain. The algorithm also compares favourably with classic envelope detection techniques based on filtering and the Hilbert Transform. Besides the most direct applications of this work to audio classification and synthesis, we foresee impact in compression techniques and machine learning approaches to audio. The discrete curvature definition presented could also be extended to three-dimensional settings, to improve shape detection algorithms based on alpha-shapes.

Keywords: DSP, alpha-shapes, envelope detection, discrete curvature

1 Introduction

Envelope detection is ubiquitous in both analogue and digital signal processing (Caetano & Rodet, 2011). Nevertheless, the literature in this area is very fragmented (Lyons, 2017). Besides, most envelope detection techniques are designed to account for very specific settings, like pure sinusoids with moderate noise content, a limitation that excludes most physical signals, as is the case of recorded sound, for examples; that limitation arises in part by the lack of a strict mathematical definition for a temporal envelope (Meng et al., 2013).

In many natural signals, however, the temporal amplitude envelope of a signal plays a prominent role in the characteristics exhibited: according to Qi et al. (2017), for example, the envelope is at least as important as the fine structure of a soundwave in the context of the intelligibility of mandarin tones. That is also the case for English (Shannon et al., 1995), where even envelopes modulating mostly noise were still capable of conveying meaning.

The envelope helps to impart emotion and identity to the human voice (Zhu et al., 2018), and envelope preserving characteristics in concert halls are associated with their pleasantness (Lokki et al., 2011).

When dealing with broadband signals, approaches tailored to specific applications are prevalent, such as the one presented by W. Yang et al. (2014) for the distributed monitoring of fibre optic or the one formulated by Assef et al. (2018) in the context of medical ultrasound imaging.

Addressing the different units in the horizontal and vertical axes, one can transform the DSP problem of envelope detection in the geometric problem of defining the shape of a set of points in \mathbb{R}^2 . For that purpose Edelsbrunner et al. (1983) introduced the concept of alpha-shapes, a mathematically well-defined extension to the convex hull of a finite set of points, closely related to the Delaunay triangulation and Voronoi diagrams of those points.

This approach is used in areas such as the detection of features in images (Varytimidis et al., 2016), reconstruction of surfaces from a cloud of points (Wu et al., 2015) and Spectroscopy (Xu et al., 2019), with the last work, which involves the estimation and removal of the Blaze function (a kind of envelope) of an echelle spectrograph, being particularly illustrative of the potential of cross-fertilization.

Steps in the direction of translating geometric algorithms to the context of envelope detection were also made by C. Yang, Tiebe, et al. (2015) with an approach based on the construction of a skeleton underlying the wave, and with the direct translation of computer vision methods to the task (C. Yang, Grzegorzek, et al., 2015).

Following this path, we present a general approach to envelope detection, exploiting the intrinsic characteristics of a generic, spectrally complex wave in order to avoid the need for manual intervention or parameter tuning.

While the robustness of the proposed approach allows it to be used as a plug-in replacement for many methods encountered in the literature, we feel that it would be particularly useful for sound synthesis; the envelope is shown to add complexity to the spectral representation of a wave (Tarjano & Pereira, 2019), and an accurate description of the envelope, while solving the problem of the evolution of the instantaneous amplitude of a signal in time, would also greatly simplify further spectral analysis. Moreover, the algorithm naturally divides a signal in its pseudo-cycles, pinpointing them in the time domain, providing the building blocks for the reconstruction of the fine structure of the wave.

The rest of this paper is developed as follows: After explaining and defining the various entities used subsequently, of which the concept of frontiers is arguably the most important, in the methodology section, we dedicate a section to present a new discrete curvature estimation approach.

We then proceed to illustrate the results of the application of the algorithm in a set of six diverse sound waves, ranging from voice to unpitched instruments comparing, afterwards, its performance with that of some classic digital envelope estimation algorithms, both from a visual and numerical standpoint.

We then discuss the implications of the work, emphasizing the focus on the construction of new interpretations of the relationship between time domain and frequency domain sound descriptions, and our vision of the impact of this methodology in the field of sound synthesis.

2 Methodology

In this work it is assumed, without loss of generality, that one is interested in retrieving the mathematically ill-defined (Meng et al., 2013) temporal envelope of an arbitrary physical sound wave, of which only a digital representation is available.

Naturally, due to the necessary truncations both in time and amplitude, as well as measurement errors introduced by the instruments used to record the signal, it is not possible to exactly recover the original, continuous wave, from its digital counterpart.

The best representation one can hope to get of the original wave is, then, the recording. It is sensible, thus, to characterise the envelope of that wave in terms of a subset of the exact samples that comprise the digital representation.

To that end, this work will emphasize the concept of frontier, as the points of the digital wave that mark the wave’s upper and lower boundaries; from those points an envelope, conforming to the vague definitions of uniqueness and smoothness, can be trivially constructed.

We start by defining a pulse as a series of consecutive samples in a discrete wave with the same sign. More formally, let $W[i] \in \mathbb{R} \forall i \in \mathbb{N}_0$, $i < n \in \mathbb{N}_0$ be a real, discrete and finite signal indexed, without loss of generality, over an adjacent subset of the natural numbers starting at zero. This definition relates closely to the concept of an array or vector in most programming languages, and is used in the interest of simplicity.

A pulse $P[j], j \in \mathbb{N}_0, j < q$ in W can then be defined as a sequence of samples indexed by i such that $\text{sign}(W[a-1]) \neq \text{sign}(W[a]) = \text{sign}(W[a+1]) = \dots = \text{sign}(W[b-1]) = \text{sign}(W[b]) \neq \text{sign}(W[b+1]) \forall i, a \leq i \leq b, b \in \mathbb{N}_0$.

In other words, each pulse is a unique subset of W with its members being the maximum sequence of samples in W with the same signal and $P[0] \cup P[1] \cup \dots \cup P[q-1] = W$. It is convenient to attribute to each pulse a pair of coordinates: those will be the coordinates of the sample with the maximum absolute amplitude in each pulse, being denoted by $P[j]_x$ and $P[j]_y$; additionally, the length, or cardinality, of a pulse will be denoted by $\#P[j]$.

Naturally, each pulse can be classified as positive ($P[j]^+$) or negative ($P[j]^-$), based on the sign of its samples, which must be the same. For an arbitrary continuous function, then, a pulse would correspond to the pieces between its roots, and would be equal to half the cycle of a sinusoid. Thus, in our definition, two consecutive pulses, naturally with opposing signs, have the potential to delimitate a pseudo-cycle, as illustrated in figure 1. For that to be true, however, the pulses need to make part of the frontiers of the signal, as yet to be defined.

The most mathematically sound definition of an envelope involves its representation as an analytic signal, introduced by Gabor in 1946 (Hahn, 2007). In his work, Gabor (1946) applies the then relatively new mathematical machinery of the quantum mechanics to unify time and frequency representations of a wave, showing how the Hilbert transform could be applied to a real signal in order to obtain an equivalent complex signal, later known as the analytic signal.

This analytic signal is of the form $a(t) = s(t) + \mathbb{H}(s(t)) i$ (He & Dellwo, 2016) where $s(t)$ is the original real signal, that becomes the real part of the analytic signal. $\mathbb{H}(s(t))$, the Hilbert transform of the original signal becomes, then, the imaginary part of the analytic signal; the envelope of a signal thus represented can be straightforwardly obtained by the computation of its complex modulus.

Figure 2 shows the envelope obtained via the Hilbert transform, for a pure sinusoid with a local frequency of 20 cycles, modulated by a polynomial of the third degree, in the presence and absence of gaussian white noise with standard deviation of 1/10 of the wave’s maximum amplitude.

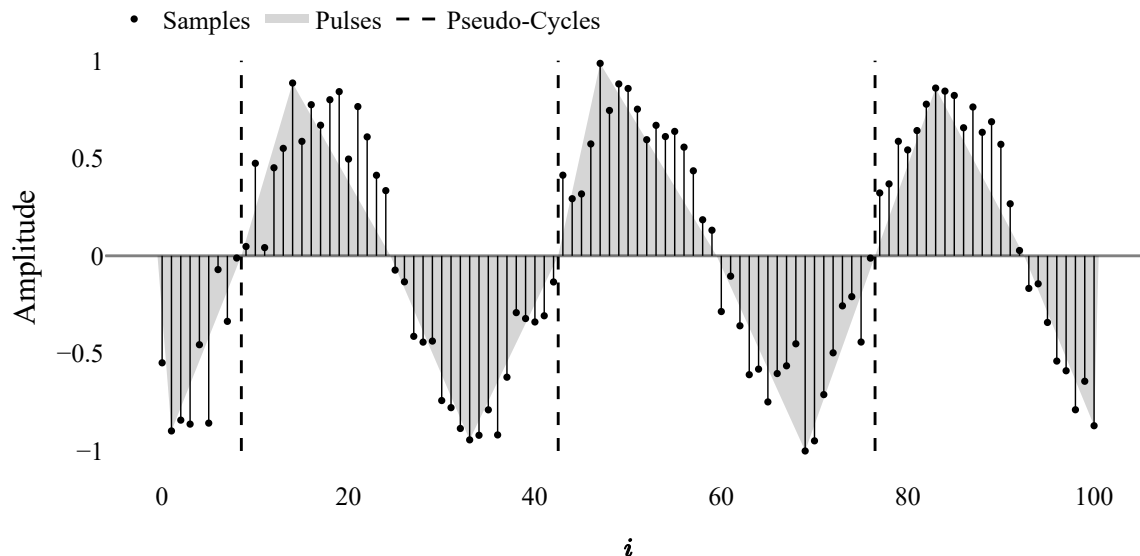

Figure 1: The grey areas encompass the simplified convex hulls of the pulses. The dashed lines mark the frontier between pseudo-cycles.

Figure 2: Envelope of a pure sinusoid modulated by a polynomial of degree 3, as obtained by the Hilbert Transform. In the first half, the sinusoid is free of noise, while in the second half white gaussian noise with a standard deviation of 1/10 of the maximum amplitude of the wave was added to the base signal.

It is readily noticeable from figure 2 that, as soon as noise is introduced in the original signal, it is reflected in the envelope, breaking our assumption of smoothness. Other than that, this definition yields a unique, positive envelope. In practice, however, is not uncommon for a discrete wave, especially in the case of sound, to present somewhat different positive and negative contours; as our method will forcibly have to be applied separately to both sides, superior and inferior, of the discrete wave, it is only natural to introduce such separation as soon as possible.

To do so we will define the positive (upper) frontier and negative (lower) frontiers of a discrete wave as the set of points $(i, |W[i]|)$ that are, necessarily but not sufficiently, the points of maximum absolute amplitude of their respective pulses.

The set of all these points such that $W[i] > 0$ will be called the positive, piecewise linear frontier and will be denoted by F^+ ; similarly, F^- will denote the negative frontier of W , defined by the subset of points $(i, W[i])$ where $W[i] < 0$, as is shown in figure 3.

To identify such points, we need to address the different units in which the amplitude and horizontal distance of our wave are expressed.

To make abscissa and ordinate units consistent for the computation of the frontiers, and proceed with a geometric treatment of the subject, we consider the set of positive and negative pulses separately.

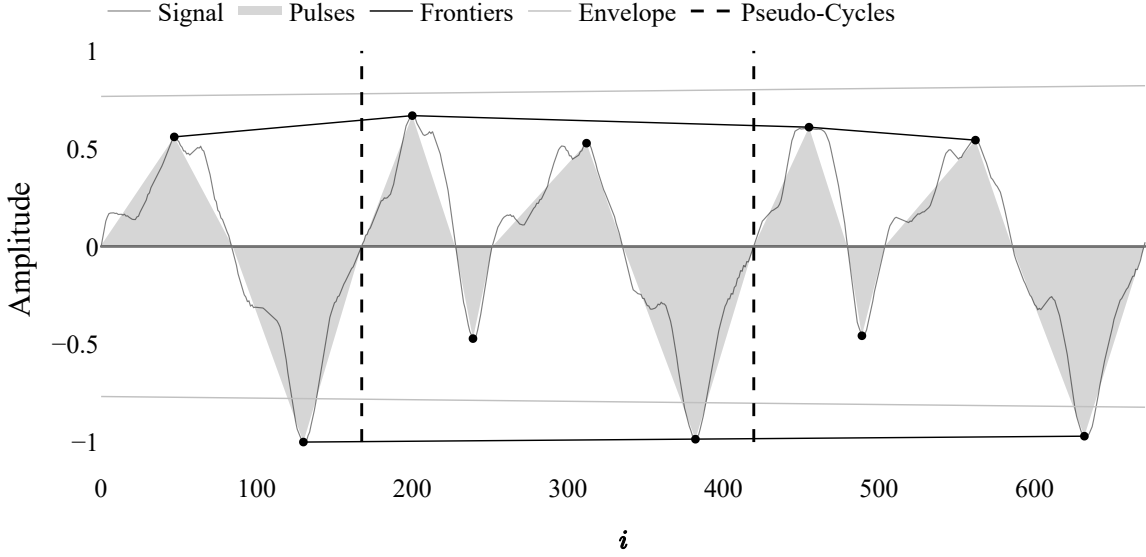

Figure 3: Positive and negative frontiers, envelope and pseudo-cycles for a fragment of piano sound. While we have only one (positive) envelope, here mirrored in the inferior space, we have two frontiers, the superior and inferior.

For each set, we multiply all pulses lengths by the average length of the pulses in the set, after having divided by the average of the pulses' amplitudes, putting both axes in the same unit i , related to time by the equation $i = t \text{ fps}$.

Formally, supposing we have m pulses with the same sign, we scale each pulse's vertical coordinate $P[j]_y^\pm$ by s^\pm , where:

$$s^\pm = \frac{\sum_{j=1}^m \#P[j]^\pm}{\sum_{j=1}^m P[j]_y^\pm} \quad (1)$$

Because we are interested in approximating a function that is smooth over the whole domain of the wave, we can assume that, in the scale of a pulse, this function will be very close to a horizontal straight line and, thus, won't touch any point inside the convex hull defined by the pulse.

By the same token, as the change in amplitude from one pulse to the next pulse with the same sign is motivated by changes in this same envelope, one can reasonably suppose that $\max(P[j]) \approx \max(P[j+2])$.

That justifies the approximation of the convex hull of a pulse by the triangle defined by the points where the pulse crosses the horizontal axis and the point of maximum amplitude; this will allow a considerable dimension reduction as this triangular pulse can become the atomic unit for the rest of the method.

This definition also makes clear that only one point of an arbitrary pulse can be in the frontier, namely, its point of maximum amplitude; those definitions will allow us to derive the frontiers of a wave using an alpha-shapes inspired algorithm without the need to compute the Delaunay triangulation first.

Translating the intuitive explanation of alpha-shapes in Edelsbrunner and Mücke (1994) to our context, we can say that the points in the frontier are those touched by a circle outside the signal that is not allowed to contain any point of the signal; The pulses that contain said points can be seen as frontier pulses.

Intuitively, one can picture a circle being rolled above (or below, in the case of the negative frontier) the signal, and marking the points it touches as frontier points.

We can therefore revisit the concept of a pseudo-cycle, only hinted at before, defining it as the samples of the original wave that belong to two successive pulses that in turn belong to their respective frontiers, including eventual pulses between them, as can be seen in figure 3.

It is now necessary to infer the appropriate radius of such a circle and, to that end, a measure of the curvature of a discrete function is needed. Discrete curvature estimation is an important task in image processing (Fleischmann et al., 2010) for which no default definition exists.

The two possible general approaches are the derivation of direct methods that use characteristics of the discrete wave to calculate its curvature at each point, or the calculation of the curvature of a curve fitted to the discrete wave (Coeurjolly et al., 2001).

To fit a polynomial to a generic wave two approaches are readily available: the least mean squares approach, that seeks to minimize the dependent variable errors and the total least squares problem, that treats both variables symmetrically (Golub & van Loan, 1980).

The geometric, symmetrical nature of the problem excludes the more computationally economic least mean squares approach, however, leaving us with the total least squares, for which no general closed-form solutions are available (Markovsky & Huffel, 2007); this leads us to turn our attention to direct approaches of curvature estimation.

2.1 Discrete Curvature Estimation - The Equivalent Circle Approach

As previously noted, no default discrete curvature definition exists; Carroll et al. (2014), for example, derives three such different definitions based on the approximation of a circle by an inscribed, centred and circumscribed polygon. In the context of 3d meshes, Váša, Kühnert, et al. (2016) evaluate a range of existing estimators from a multivariate point of view.

For our needs, however, it is more convenient to define our own discrete curvature estimator; the approach here presented differs from most others found in the literature in that the curvature is defined over the edges linking the points that form the discrete wave, instead of the vertices.

To that end we are going to apply the definition of smooth curvature as the rate of change of the unit tangent to a curve, noting that this is equivalent to that of the osculating circle (Váša, Vaněček, et al., 2016).

The idea is to find the equivalent circle whose tangent presents the same change in direction, in the same horizontal distance, as the edge of interest, as shown in 4. This approach has the convenience of estimating the radius directly.

Figure 4: Change of direction from horizontal, in \hat{u}_0 , until an angle of θ , in \hat{u}_1 , that is equivalent to the angle between the average direction and the direction of the vector \vec{v}_l whose radius of curvature is being calculated, shown in the picture in grey.

For each frontier, the angle θ between the average direction and each of the vectors can be obtained via the relation between the slopes of the respective lines, as in the expression $\theta = \arctan((m - \bar{m})/(1 + m\bar{m}))$, with $\bar{m} = \sum_{l=1}^{m-1} (P[l+1]_y - P[l]_y)/(P[l+1]_x - P[l]_x)$ and $m_l = (P[l+1]_y - P[l]_y)/(P[l+1]_x - P[l]_x)$

The radii of the equivalent circles are thus given by $r_l = x_l/\sin(\theta_l)$ with the curvature given by $\kappa_l = 1/r_l = \sin(\theta_l)/x_l$, where $x_l = P[l+1]_x - P[l]_x$ and $y_l = P[l+1]_y - P[l]_y$. Joining both equations, one can write:

$$r_l = \left| \frac{x_l \sqrt{\bar{m}^2 + 1} \sqrt{x_l^2 + y_l^2}}{\bar{m}x_l - y_l} \right| \quad (2)$$

After this procedure, illustrated in figure 5, two sets of points in \mathbb{R}^2 , corresponding to the positive and negative frontiers, are obtained, where the ordinates represent the instantaneous radius, with its localization in the time domain given by the abscissas.

Given the robustness of the method, for an average wave of a few seconds at an ordinary rate of 44100 *fps* the average of the radius values is sufficient to assure the accurate identification of the frontier.

However, a curve fitting method can be used in the case of longer or ill-behaved waves. An example of the use of the average equivalent circle can be seen in figure 6.

3 Results

Figure 7 illustrates the frontiers of six diverse discrete sound waves, as well as an in-detail view of a shorter segment for each signal. All waves used are records of physical sounds, chosen to represent the applicability of the algorithm in real-world scenarios.

We can see that the frontier is satisfactorily detected in the case of harmonic and inharmonic sounds, and presents robustness concerning the number of samples and the frequencies of the waves.

Besides, the algorithm provides the position of the pseudo-cycles of a wave, with which one can, for example, derive its fundamental frequency and phase: using one of the two frontiers, we have $f = (\#F^\pm - 1)n/(F^\pm[-1] - F^\pm[0])$, where $\#F^\pm$ denotes the cardinality of the frontier, while $F^\pm[0]$ and $F^\pm[-1]$ stand for the frontier's first and last item, respectively.

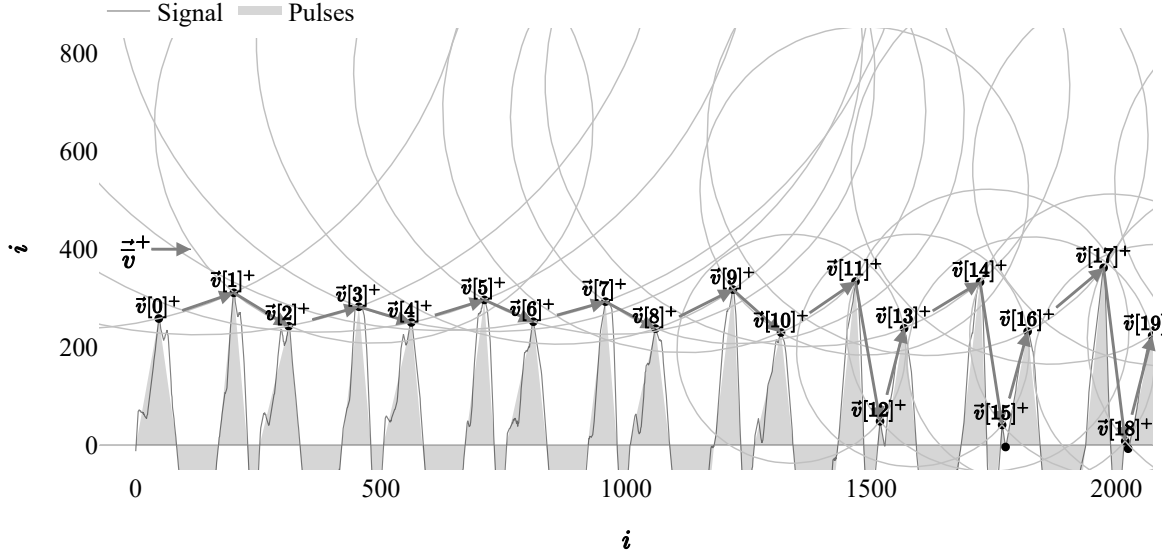

Figure 5: The equivalent circles obtained via the procedure described for the positive frontier. θ , the angle between \vec{v}^+ and each of the \vec{v}_i^+ is used, as is the horizontal component of each \vec{v}_i^+ to obtain the radii of the circles.

Figure 6: The positive frontier as obtained by the use of the circle representing the average curvature of the discrete wave illustrated.

Similarly, each item of each of the frontiers can be used to estimate the local phase at that location. For the positive frontier, it is necessary to note that, for each item, the following equation holds: $\cos(\phi + 2\pi fi/n) = 1$, and thus $\phi = k 2\pi - 2\pi fi/n$, with $k \in \mathbb{N}$, while for the negative frontier $\cos(\phi + 2\pi fi/n) = -1$ and $\phi = k 3\pi - 2\pi fi/n$.

The impact of the normalization of a wave using the frontiers obtained can be seen in figure 8, which shows the original and normalized wave in the case of a recording of the key 33 of a piano both in the time and frequency domains. We can see that the Fourier power spectra is greatly simplified in the case of the normalized wave.

3.1 Robustness

Figures 9 and 10 illustrate the computational resilience of the algorithm for scaling in both the abscissa and ordinate axes, respectively. This is due to the normalization scheme presented in equation 1.

Although important from a theoretical standpoint, this step has an especial computational relevance in the case of digital sound waves, as they tend to be composed of a high number of samples with relatively low amplitudes, generally normalized between -1 and 1, leading to a numerical disparity between axes.

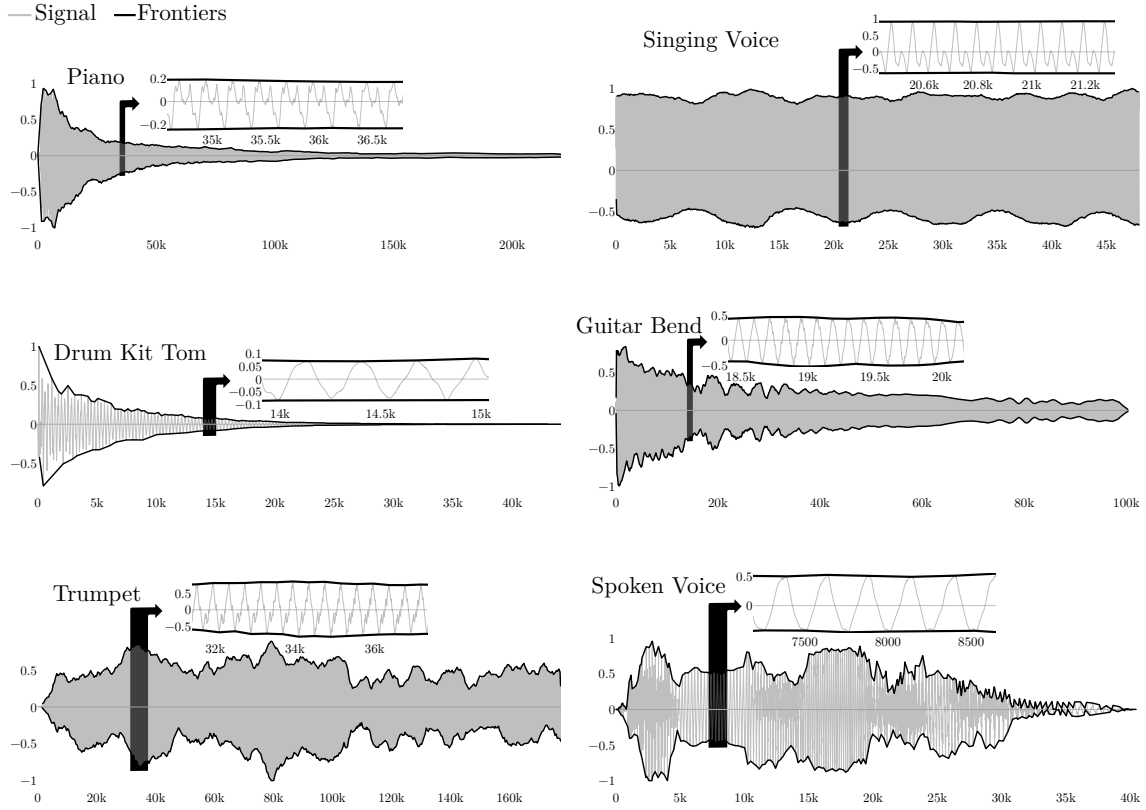

Figure 7: Positive and negative frontiers of six digital waves, as extracted by the algorithm here presented. For each wave, the region highlighted in black is shown in detail besides the whole wave. For each wave the horizontal axis is the sample number i , while the vertical axis is the normalized amplitude. All 6 waves were recorded at 44100 *fps*.

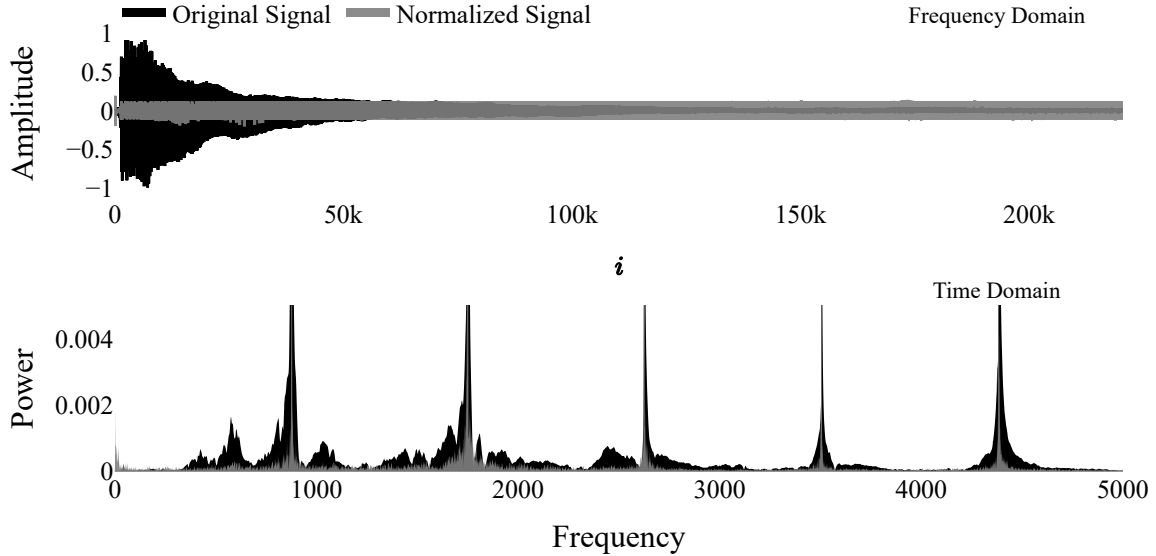

Figure 8: Original and normalized views of a recording of key 33 (F3, 175 Hz) from a grand piano both in time and frequency domains.

3.2 Comparison with traditional algorithms

Direct comparison with many of the more recent algorithms is made difficult by the unavailability of digital implementations of such works, many designed to process analogue signals (e.g., Assef et al., 2018).

Nevertheless, insight can be gained from a comparison of the results of the method here proposed with some of the most common envelope extraction algorithms, as can be seen in figure 11.

For a recording of a guitar bend, we contrast the proposed algorithm with four common approaches of varying complexity: simple smoothing of the rectified original wave, low pass filtering followed by rectification, peak identification and subsequent

Figure 9: Minimum and maximum scales of the abscissa before computational stability issues arose, for a recording of a drum kit tom. $B = 10^6$.

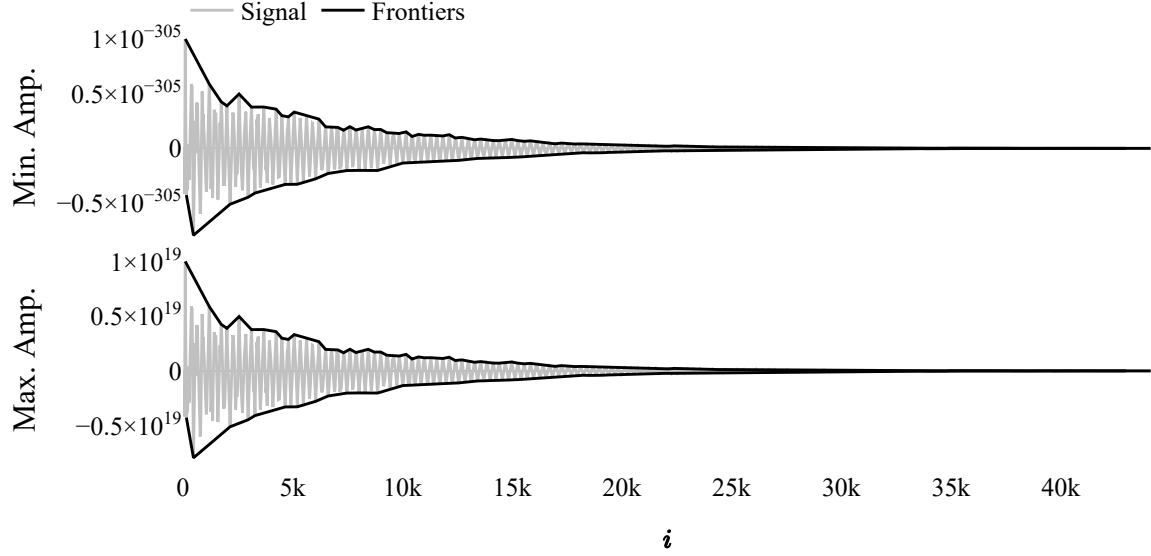

Figure 10: Minimum and maximum values of the amplitude before computational stability issues arose, for a recording of a drum kit tom.

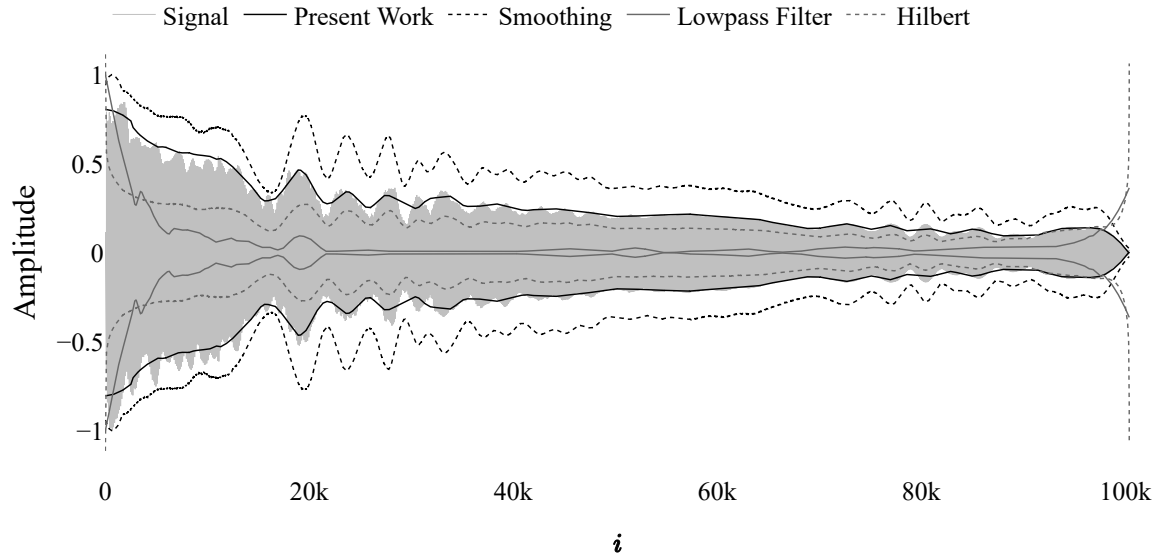

Figure 11: Comparison of the algorithm present in this work with the most common methods of digital envelope identification.

smoothing, and the extraction of the envelope via Hilbert transform, as presented earlier in the paper, with a previous smoothing of the original wave to avoid the artefacts shown in figure 2.

All those methods demanded careful choice of parameters: in the case of filtering, a cut-off frequency of approximately 88

Hz was used, consisting of one additional parameter to be tuned. For all the other traditional approaches, the Savitzky-Golay smoothing algorithm was used, and the window size was the parameter to be defined.

In the case of the proposed algorithm, the smooth temporal envelope was obtained merging both positive and negative frontiers, that were also smoothed with the same procedure described. Figure 12 illustrates this process.

Figure 12: Original positive and negative frontiers in dark grey and their mirrored versions. The temporal envelope, in black, is obtained by merging and approximating both frontiers.

Table 1 presents a computational comparison. The times are for custom implementations of those methods in the Python programming language. The least mean squares result was calculated by halving the envelopes presented in figure 11 and comparing them with the rectified absolute wave, so as to avoid the potential influence of an estimated frequency.

We can see that, while the algorithm here presented is the most accurate, it's also the most computationally intensive. The connection between alpha-shapes and Delaunay triangulation can be explored in future works as a means to improve the efficiency of the algorithm.

Method	LMS	time(s)
Presented Algorithm	0.0088	4.1507
Smoothing	0.0123	0.1911
Low pass Filter	0.0258	0.5601
Hilbert Transform	0.0141	0.2599

Table 1: Comparison of the algorithm present in this work with the most common methods of digital envelope identification.

4 Discussion

This work hopes to fill a gap identified by the authors in the context of sound synthesis, where the lack of procedures for the accurate identification of the temporal envelope of arbitrary waves consists of an obstacle to the complete description and eventual manipulation of signals.

While relevant in its own accord, the procedure here presented isolates the individual pseudo-cycles of a wave, pinpointing them in the time domain. Due to that, a rich set of theoretical advancements, of whose an example was given in the preceding section, can be built upon this initial algorithm.

With the knowledge of the exact position and characteristics of the pseudo-cycles of a wave, one can investigate its evolution in time, in terms of waveform, for example, free from the potential interference of a modulating wave; in other words, one can have a very satisfactory view of the instantaneous shape and phase of an arbitrary wave and its evolution in time, providing a way to bridge the gap between time domain and frequency domain interpretations.

In the context of sound synthesis, for example, one would be able to apply specific methods for the recreation of the envelope, more in line with its smooth, slow varying and non-periodic nature and a different approach to the periodic and relatively fast changes of the temporal fine structure.

4.1 Conclusion

It is our opinion that such theoretical advances can be used in the formulation of better representations of discrete sounds, that in turn can improve sound compression techniques, while providing more adequate representation for the application of machine learning techniques for both sound classification and synthesis.
